## PUBLICATIONS OF RUSSELL SAGE FOUNDATION

*Russell Sage Foundation was established in 1907 by Mrs. Russell Sage for the improvement of social and living conditions in the United States. In carrying out its purpose the Foundation conducts research under the direction of members of the staff or in close collaboration with other institutions, and supports programs designed to improve the utilization of social science knowledge. As an integral part of its operations, the Foundation from time to time publishes books or pamphlets resulting from these activities. Publication under the imprint of the Foundation does not necessarily imply agreement by the Foundation, its Trustees, or its staff with the interpretations or conclusions of the authors.*

# Foreword

As far-reaching change takes place in American society, the social science community and those concerned with public policy and intervention increasingly seek data relevant to an examination of social change. In anticipation of this twofold demand for systematic data and analysis, the Russell Sage Foundation instituted a program of study on "social indicators" in 1965. *Indicators of Change in the American Family* is the third in a series of publications resulting from this program effort.

The first volume of the series, *Indicators of Social Change* (1968), edited by Eleanor Bernert Sheldon and Wilbert E. Moore, presented a general framework for the analysis and measurement of change. *Indicators of Trends in American Education* (1969) by Abbott L. Ferriss, the second in the series, presents the principal time-series data basic to the description and analysis of changes in American education. In *Indicators of Change in the American Family*, Dr. Ferriss has provided us with a selection of some existent and some new measures of family change. This assemblage of indicators on a fundamental institution illustrates both the value of analyzed time-series data and the innovative utilization of these data in examining social change. It is anticipated by the author and by the Foundation that the materials presented will be an important data resource to researchers and others; we trust that it will stimulate others to develop new approaches to and refinements of social reporting and social measurement.

# Acknowledgments

The data here presented have been compiled from published sources, brought up to date with recent, unpublished data obtained through courtesy of a government agency. The United States Bureau of the Census, the United States Bureau of Labor Statistics, and the Division of Vital Statistics of the National Center for Health Statistics have been especially helpful. Mrs. Carol O'Shaughnessy assisted in bringing together many of the statistical series and in editorial tasks; and Mary Ann Ferguson typed the manuscript.

## Introduction

These statistical data on critical trends in the family are bounded by two limits: (1) what is available, and (2) knowledge of what reveals significant trends. Both what is available and what is revealing, then, constrained selections for this small collection of data on the family.

Although a great deal of data may be available on the family, not all of it is periodically collected to produce time series. Time series are essential if one is to track changes in the institution, in family characteristics relative to other social changes, and to trace the direction the institution is following into the future. Most of these time series were assembled by the United States Bureau of the Census and the Division of Vital Statistics, National Center for Health Statistics, and many of them have been analyzed in American Families (Glick, 1957) and in Marriage and Divorce: A Social and Economic Study (Carter and Glick, in press, 1970).

Identifying what is significant, even more, is a limitation and a boundary. Out of a theoretical understanding of structural relationships and of underlying primers and movers of change, one might first identify the most relevant factors to be measured and watched as social indicators of the family; then, one might select such measures with the assurance that their trend signifies changes of consequence. But without adequate theoretical understanding--which unfortunately is

lacking (Goode, 1968: 295-348)--one must select indicators upon the basis of other norms and standards, such as those that help identify social problems or tell us what is good or bad.

Most of the social indicators on the family presented here have been extracted from published sources and are reproduced as they originally appeared. A few other indicators have been contrived from available data, however, in an attempt to create more sensitive indicators. Examples of contrived indicators are the marriage cohort divorce rate and the changes in illegitimacy rates by age groups.

The statistical time series are presented and organized topically: marriage, marital status, households, fertility, dependency, divorce, work and income, and poverty. This organizing principle is convenient, but it is not entirely satisfactory. A more revealing approach might be based upon the primary functions the family performs for society: affectional, procreative, protective, recreational, socialization, and so forth; showing for each how adequately the function is performed. This possible approach was rejected because society-wide measures in time series are unavailable for many of the important functions. Another promising approach was also abandoned: the idea of organizing family indicators around underlying social changes that could be linked to observed changes in the family institution. Both of these approaches remain for future research, more adequate measures, and more comprehensive theory.

In presentation, the series are illustrated by graphs and accompanied by a brief commentary on a facing page. The statistical series are numbered in an appendix for easy identification and reference. Sources of the data are cited at the foot of the page of commentary. In exploring the social consequences of some of the changes, it was desirable to present a few tables of data in conjunction with the graphs.

The series selected for inclusion were chosen because of some apparent or assumed significant change displayed by the series. In describing these changes, suggestions are sometimes offered of the underlying causes that have brought the change about, but in no instance can it be said that the analysis presents undeniable proof of the causative link. For example, reasons for the decline in the legitimate fertility rate are suggested, but to more comprehensive analyses of fertility must be left the proof and the substantiation of the suggested bases for the change.

Finally, this attempt to assemble social indicators on the family is made to illustrate some of the utilities of analyzing changes in an institution through time series, to explore approaches to developing social indicators, and to stimulate others to improve the data, the method, and the theory underlying the study of social change.

A number of statistical series are presented at the end of the volume that are not discussed in the text. To discuss and illustrate each series would have made the text redundant,

for a trend once illustrated need not be repeated for a different age group or a different population category. Consequently, only selected series are reviewed. Others are made available to the reader, if he wishes to study them. As an example, labor force participation rates by sex and marital status are illustrated by only one age group (the 20-24 year olds). These trends must be taken as representative of the other age groups, particularly the increasing participation of married females in the labor force and the decreasing participation of single males in the labor force.

In conducting this study, numerous series were examined that have not been included. A chief reason for excluding an available series was that the series presented meager year-to-year changes. For some ages the percent of widowed males has been excluded. Although the percent of intact marriages for females by age are included, only a few age groups are discussed. The median age at first marriage by sex has been practically constant for twenty years. The percent distribution of households with male head, by age of head, shows a slow drift since 1940, but otherwise appears to be stable. The distribution of the population by household relationship also is inactive over time: 30 percent of the population persist as household heads, 22 percent are wives of heads, 46 percent are other relatives of heads, etc. Such constant parameters undoubtedly belong in any definitive discussion of the family, but there is less rationale for including them in a study that searches for change.

Series are also excluded from the volume for other reasons; for example, series reflecting the farm-nonfarm residence of households are omitted because farm households have become a small and fairly stable part of the total (5 percent).

Other data have been neglected also. Data on family income, to cite one example, are represented by only a few series; to present the bulk of income data would have doubled the size of this volume and would have introduced a great deal of redundancy. The analyst interested in family income and expenditures will find the data readily available in the publications of the Census Bureau. The topic is more properly understood in relation to the economy than to the family institution.

Housing data, too, have been neglected. The tenure of occupied dwelling units, the adequacy of housing as gauged by housing standards, and the facilities and equipment within the household are not without social significance. There are problems, however. Previously used criteria of housing adequacy are undergoing revision. Tenure, facilities, and equipment, isolated from relevant social factors, provide indicators of affluence or of need in our society, but they do not indicate the status of social relations in the institution.

Very little use is made of decade-by-decade statistics from the decennial censuses. Such data are analyzed in the

Census Monograph Series (e.g., Glick, 1957). Our preference for indicators that are available more frequently than every ten years may be defended as an attempt to identify trends soon enough in time to signal what is to come, and, as a general rule, annual data are required for this.

Finally, the study was set up to exploit published and readily available data. It was not designed to enter the files of prior surveys to contrive new statistics and new measures. This task sorely needs to be done. It will require large resources for trial tabulations, analysis, and so forth.

To contrive new measures on the family two approaches hold great promise: (1) the exploitation of available data that has been collected through regular, periodic surveys; and (2) the collation of data collected through registration and through administrative routine. These two possibilities will be illustrated briefly.

The two surveys that hold exceptional promise for developing measures of the family are the Current Population Survey and the Health Interview Survey. The Current Population Survey, for example, consists of rotating samples of households (four months on, eight months off, four months on again). In the course of its tenure on the CPS, a household typically contributes much information about itself that could be assembled as a household file. Events reported by the household over this four-month period may be used to

classify the household in relation to other events. Some examples are the use of family stage as a classificatory variable, the examination of simultaneous unemployment of household members, the continuing inability to work, fluctuations in household composition, stability or instability of household personnel. Such measures might be studied in relation to school enrollment, educational attainment, the number of children ever born to women, mobility, and the like. Measures also can be contrived by aggregating information from the several households in the primary sampling unit. Such innovations require trials, experimental manipulation of the basic records, study of the sampling procedures, and, above all, time. The richness of the Current Population Survey files, and of the Health Interview Survey files as well, should not remain unmined in the face of the widespread demand for social indicators that might reveal directions for needed social programs.

Registration data and data accumulated through administrative routine possess equal potential, but the problems of linking the several files and of interpreting the results are greater. Marriage registration, birth, death, and divorce records, Social Security files, the National Register of Scientific and Technical Personnel, school records, and a number of others may potentially be assembled to produce series of great analytical value. The primary problem is linking the data so that individual privacy is held inviolate. There remain administrative, legal, and ethical issues to be resolved before such files can be established and used in the interest of statistical time series.

## MARRIAGE

### The Marriage Rate, 1940-1968, and a Sex Ratio, 1950-1975

Marriages per 1,000 unmarried women, ages 15 to 44 years, are shown in the accompanying chart (Series 1). The predominant influence of World War II upon the marriage rate is illustrated by the initial increase in the rate to 1942, followed by a decline to 1944. Marriages that were delayed because of the war were consummated immediately afterward, accounting for the great increase in the rate in 1946. The marriage rate continued at a fairly high level during the 1950s, although it was declining, and reached a low point in 1962.

Also presented on the graph is the ratio of males 20 through 26 years of age to females 18 through 24 years, from 1950 to 1975 (Series 2). Of all men who marry for the first time, about two-thirds are within the ages 20 through 26 years, and of all women who marry for the first time, approximately three-fourths are within the ages 18 through 24 years. The ratio of these two population aggregates provides an index to relative opportunity for a female within these ages to find a mate of a suitable age. It appears to bear some relationship to the marriage rate, perhaps leading the marriage rate by one year. For this reason the ratio is extended to 1975 as a predictor of the possible trend in the marriage rate. From this indicator one might anticipate that the marriage rate will dip to a low point in 1970 or 1971. Being currently below 100, the ratio reflects a deficit of males in relation to females for the ages represented. This deficit will continue until 1981.

15–44 Years

**Figure 1.** Total Marriages per 1,000 Unmarried Women 15–44 Years of Age, 1940–1968, Series 1, and Ratio, Males, 20–26 Years of Age, to 100 Females, 18–24 Years of Age, 1950–1975, Series 2

## MARITAL STATUS

### Marital Status of the Female Population 15 Years of Age and Over, 1940-1968

While the percentage married of the female population increased slightly during World War II, it increased rapidly in the immediate postwar period, from 1946 to 1949. In the eleven years after 1949--that is, to 1960--the percentage married remained fairly constant at approximately 67 or 68 percent. Since 1959 the percent married has declined approximately 0.3 percentage points each year, fairly uniformly. The decline in percent married has been noticeably greater among females younger than 25 years and older than 65 years.

During the 1940-1965 period, the size of single year-of-age cohorts has changed considerably. Since marital status is highly associated with age, some of the change in the overall percent of the females married may be due to a change in the age composition of the female population. Consequently, the age-specific percentages married of the female population were applied to a standard million to produce a percent married standardized for age.

When standardized for age, the percent married increases in a pattern similar to the unstandardized percentage. After 1950, however, the standardized rate continues to increase, reaching a peak in 1959. Since then the standardized rate has been relatively constant, between 67 and 68 percent. One may infer, then, that the slight decline in the unstandardized rate during the past ten years results from a shifting of the female population into ages slightly more likely to be single.

Age-specific rates for the recent years (1960 to the present) show a distinct decline in the percent married of females 15-19 years, 20-24 years, and 65 years of age and over. On the other hand, percent married of age groups between these extremes show either stability or slight increases, 1960 to the present.

Source: Series 3 and 4 are computed from National Center for Health Statistics (1968a: Tables 4 and 5, pp. 26-27). Data for 1964-1968 are computed from unpublished data from the National Center for Health Statistics; for population estimates for these years, refer to Census (1968b) and Census (1969a). The female married and unmarried population is based upon Census enumerations on April 1 for decennial census years and on population estimates as of July 1 for other years. The estimates are based upon sample surveys when available. Standardized rates are based upon the age distribution of the 1960 resident female population (Census, 1963b: Table 158, pp. 1-359).

**Figure 2.** Marital Status of the Female Population 15 Years of Age and Over, and Marital Status Standardized for Age, 1940–1968, Series 3 and 4

## Marital Status of the Female Population, by Five-Year Age Groups, 1940-1968

The figure presents the percent married of the female population by age groups, arranged in non-overlapping cohorts (Series 5-10). Thus, the line beginning at the 1940 ordinate is the percent of females aged 15-19 years who were not single in 1940. The "b" on the 1945 ordinate represents the percent of the same cohort who were then married. Finally, the position at "f" on the 1965 ordinate represents the percent of the same cohort who were not single at age 40-44 years. Widowed and divorced women are counted as single. Both the married and the total populations are based upon sample surveys for the intercensal years and hence are subject to sampling error. Data for 1940, 1950, and 1960 are from the decennial census.

The trend is for slightly larger percentages married of each age group, the peak for each cohort being the 30-34 year-old group. The figure also illustrates the trend toward slightly earlier age at marriage, and the trend toward higher proportions of the female population who are married at each successive age group. The latter may be most readily observed in the figure by following each letter successively across time. It will be noted, however, that the increments for the 25-29 age group and for the 30-34 age group are quite small.

The percentage married in the 40-44 age group exceeded slightly the percentage of the same cohort married five years earlier (at age 35-39 years) until sometime between 1950 and 1955, when the trend reversed itself. It appears that cohorts are now reaching a peak in the percentage married during the 30-34 years-of-age period, and that thereafter smaller proportions are married. Even so, the decrement is small, being one or two percentage points. The general trend for each age group is toward larger percentages married.

Source: Series 5-12 are based upon the same sources cited for Series 3-4.

**Figure 3.** Marital Status of the Female Population, by 5-Year Age Groups, 1940–1965, Series 5–10

## Marital Status of the Population by Age, Sex, and Color, 1940-1967

The eight charts following (Figures 4 through 11) present trends in marital status of the population in percentages of the total that are married, single, widowed, and divorced for age, sex, and color categories. The widowed and divorced are not always included, since they sometimes tend to be a fairly constant proportion. The single category and the married category complement one another, the trends moving in opposite directions.

These data arise from the Current Population Survey, except the Census data for 1940 and 1950. The data for the nonwhite population, being based upon a smaller sample than that for the white population, present estimates having greater sampling error than estimates for the white population. Slightly more of the variation exhibited by the nonwhite data than the white may be due to sampling error. To show the possible effects of sampling variability, the range of the sampling error at two standard errors (the 95 percent probability level) has been introduced on the graphs for a number of the series.

A brief comment will be made on each chart, in turn.

### Marital Status of Males 14 Years of Age and Over, by Color

Figures 4 and 5 (Series 13-14, 17-18, 21-22, 25-26) show trends for white and nonwhite males. They are roughly the same, but white males are more likely to be married than nonwhite.

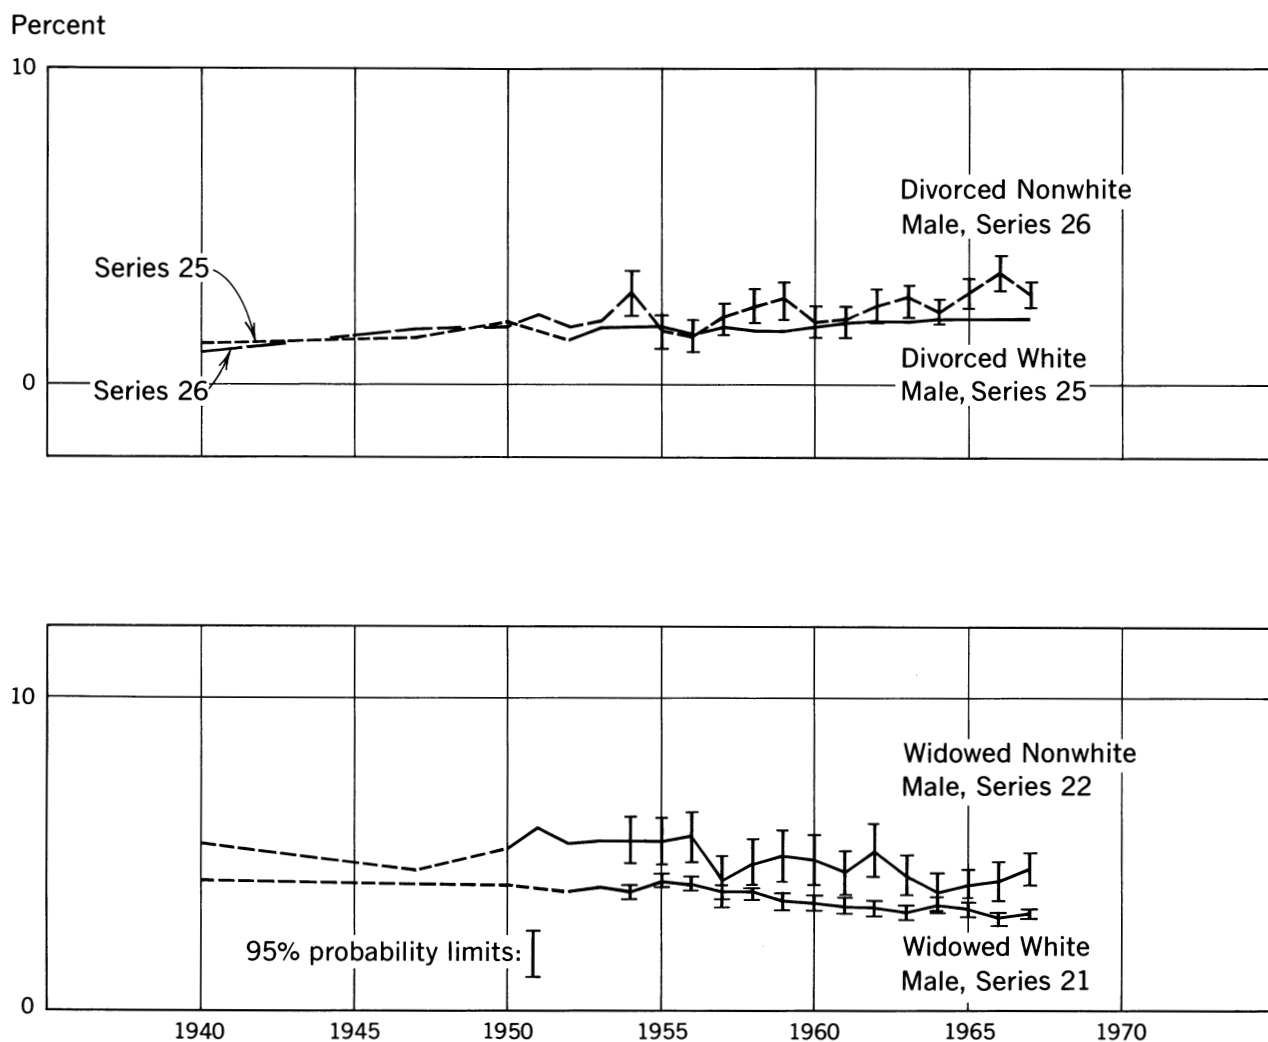

The percentage single is increasing slowly while the percentage married is decreasing. This is partly a result of the increasing proportion of the population 14 years of age and over who are below 20 years of age, the younger ages being less likely to be married.

Neither divorced nor widowed males (Figure 5, Series 21-22 and 25-26) show a variation or trend of any significance.

Source: Series 13-60 and Figures 4-11: data for 1940 and 1950 from Census (1963b: Table 177, pp. 1-436, I-437); for 1947 from Census (1948); for 1951-1967, respectively, (1952, 1953a, 1953b, 1955a, 1955b, 1956a, 1958a, 1958b, 1959a, 1960a, 1962a, 1963a, 1965a, 1965b, 1967a, 1968a).

**Figure 4.** Marital Status of Males, 14 Years of Age and Over, by Color, 1940 – 1967, Series 13 – 14 and 17 – 18, and the Standard Error of the Estimated Percentages, 1954 – 1967

**Figure 5.** Marital Status of Males, 14 Years of Age and Over, by Color, 1940–1967, Series 21–22 and 25–26, and the Standard Error of the Estimated Percentages for Divorced Nonwhite and Widowed White and Nonwhite Males, 1954–1967

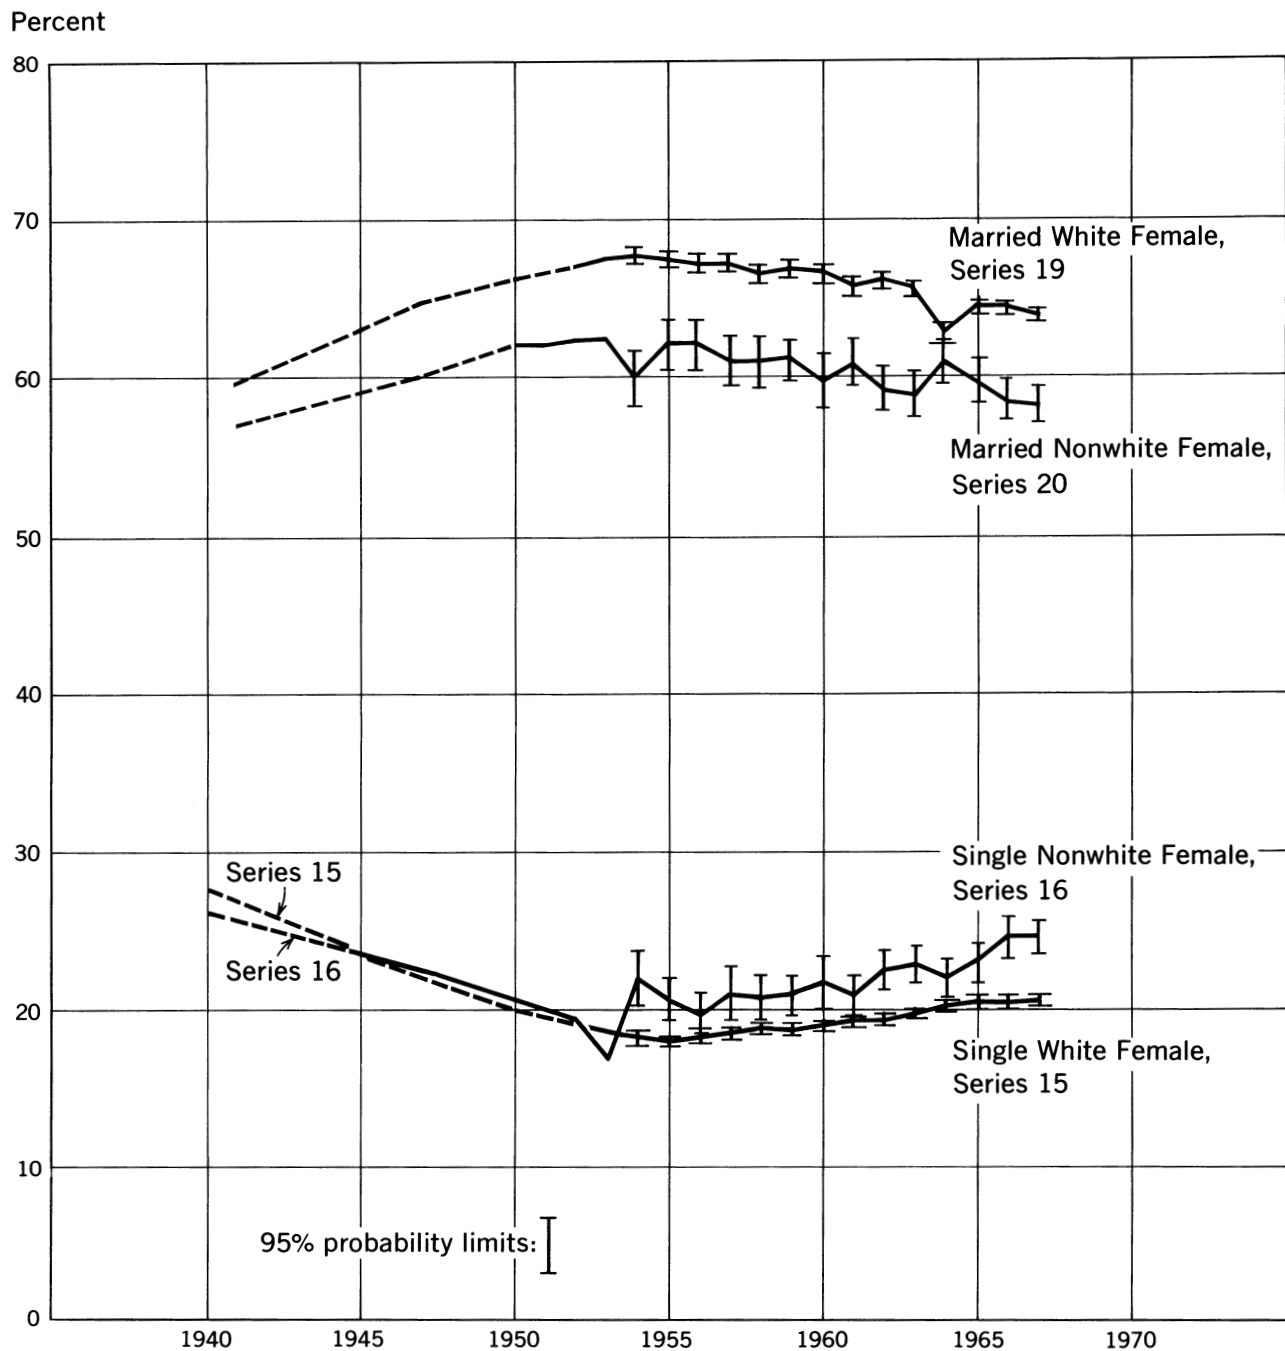

## Marital Status of Females, 14 Years of Age and Over, by Color

Trends for white and nonwhite populations shown in Figures 6 and 7 (Series 15-16, 19-20, 23-24, 27-28) are roughly the same.

Larger proportions of nonwhites than whites are divorced, widowed, and single.

The increasing percentage single results partly from the increasing proportion of the population in the younger ages.

Sources for data presented in Figures 6 and 7 are cited on page 14.

**Figure 6.** Marital Status of Females, 14 Years of Age and Over, by Color, 1940–1967, Series 15–16 and 19–20, and the Standard Error of the Estimated Percentages, 1954–1967

**Figure 7.** Marital Status of Females, 14 Years of Age and Over, by Color, 1940–1967, Series 23–24 and 27–28, and the Standard Error of the Estimated Percentages for Divorced Nonwhite and Widowed White and Nonwhite Females, 1954–1967

### Marital Status of Males, 20-24 Years of Age, by Color

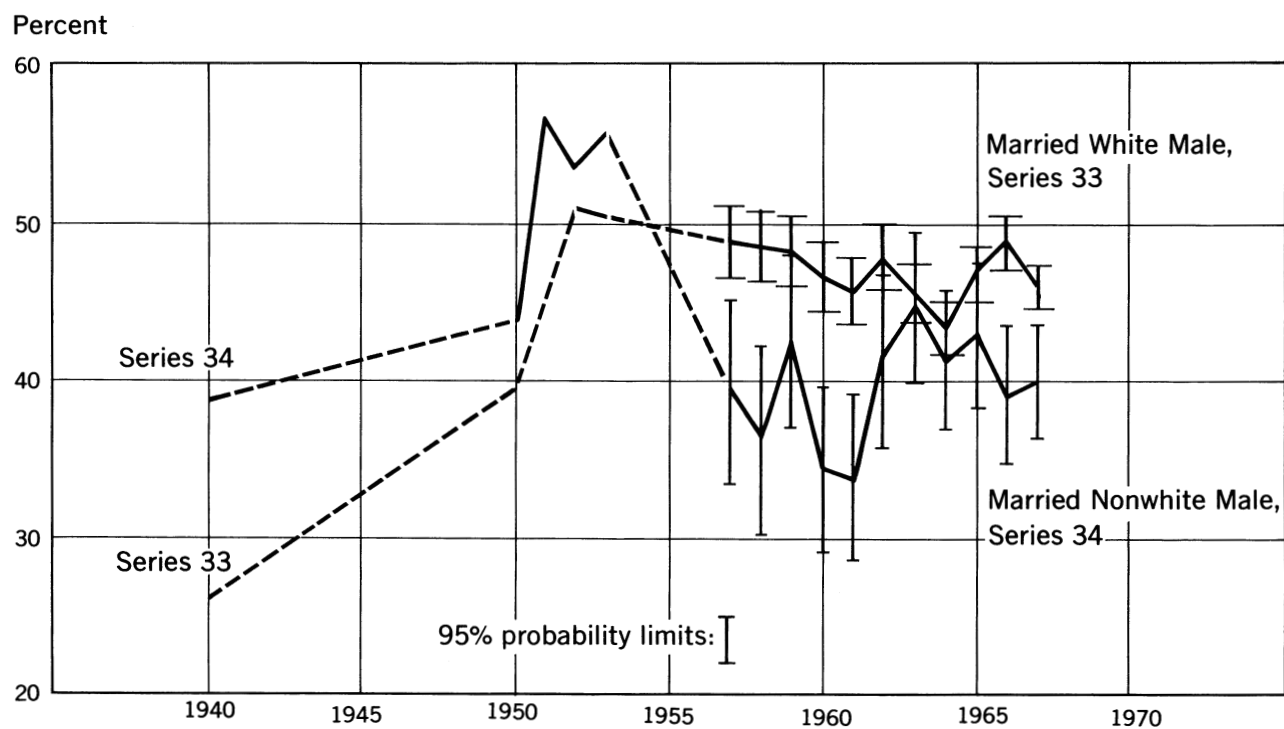

Both white and nonwhite males in the 20-24 age group are more likely to be single than married (Figures 8 and 9, Series 29-30 and 33-34).

Larger proportions of nonwhites than whites are single.

The sampling error is greater for nonwhites than for whites. The apparent irregularity of the trend, particularly for nonwhite males, may be attributed to sampling variability.

For both color groups there appears to be a slight decrease in married and a corresponding increase in single. The widowed and divorced are not shown because each is small and exhibits a relatively constant trend. (See Series 37-38 and 41-42 respectively.)

Sources for data presented in Figures 8-9 are cited on page 14.

**Figure 8.** Marital Status of Males, 20–24 Years of Age, by Color, 1940–1967, Series 33–34, and the Standard Error of the Estimated Percentages, 1957–1967

**Figure 9.** Marital Status of Males, 20–24 Years of Age, by Color, 1940–1967, Series 29 and 30, and the Standard Error of the Estimated Percentages, 1957–1967

## Marital Status of Females, 20-24 Years of Age, by Color

White females in these ages are somewhat more likely to be married than nonwhites (Figure 10, Series 35-36).

For both groups the percentage single is increasing slightly (Series 31-32).

The greater apparent variation in trend shown by the non-white than the white probably is a consequence of a higher sampling error. While the Current Population Survey is becoming more precise in estimating both groups, as may be seen from the decreasing size of the sampling error, the confidence interval still is a fairly wide band for the nonwhite series.

Widowed and divorced are not illustrated for this age group. (See Series 39-40 and 43-44, respectively.)

Sources for data presented in Figure 10 are cited on page 14.

**Figure 10.** Marital Status of Females, 20–24 Years of Age, by Color, 1940–1967, Series 31–32 and 35–36, and the Standard Error of the Estimated Percentages, 1957–1967

## Marital Status of Males, 25-29 Years of Age, by Color

For this age group, white males are more likely to be married than nonwhite males. The trends in the two series, however, are generally the same, with the percentage married increasing in both categories (Figure 11, Series 49-50).

The percentage of single males, both white and nonwhite, has been declining since about 1959 (Series 45-46).

The greater variability in the nonwhite percentages results from the smaller sample size, in comparison with the percentages for white males, and the larger sampling error for the nonwhite series. Despite the sampling error, however, the trend in percentage married is definitely increasing for both groups and the percentage single is declining.

Widowed and divorced are not illustrated, since both white and nonwhite groups are small and constant. (See Series 53-54 and 57-58, respectively.)

Sources for data presented in Figure 11 are cited on page 14.

**Figure 11.** Marital Status of Males, 25–29 Years of Age, by Color, 1940–1967, Series 45–46 and 49–50, and the Standard Error of the Estimated Percentages, 1957–1967

## HOUSEHOLDS

### The Number of Households and the Percent Husband-Wife Households, 1900-1968

As the population has grown, the number of households has increased. Household formation was interrupted slightly at the time of World War I, markedly during the Depression, and slightly during World War II and is at present (1968) entering a period of fairly rapid expansion. During the year ending March 1968, households increased 1.6 million (Census, 1968c: 1). The annual increase to 1970 will slightly exceed one million. By 1975 the number of households will be between 68 and 70 million (Census, 1968i: 2).

In 1910 approximately 31 percent of the households were on farms. By late 1968, however, the percentage on farms had decreased to less than 5 percent.

The trend in the percent of husband-wife households is also presented in the graph at right (Series 64). The percentage of husband-wife households declined during the Depression and during World War II. The percentage increased rapidly after the war and has since continued what appears to be a fairly uniform decline. This decline signifies an increase in households with male or with female head, including primary individuals who maintain a household.

Estimates of households are based upon the decennial census and relatively regular surveys beginning in 1944. Hence, the data from the mid-1940s to present are more reliable than the interim-decade estimates prior thereto.

The United States Bureau of the Census defines household:

A household includes all of the persons who occupy a house, an apartment, or other group of rooms, or a room, which constitutes a housing unit. A group of rooms or a single room is regarded as a housing unit when it is occupied as separate living quarters; that is, when the occupants do not live and eat with any other persons in the structure, and when there is either (1) direct access from the outside or through a common hall, or (2) a kitchen or cooking equipment for the exclusive use of the occupants. The count of households excludes persons living in group quarters, such as rooming houses, military barracks, and institutions. (Census, 1968c: 2.)

Source: Series 61-64: data for 1900-1958 from Census (1959b); for 1959-1961 from Census (1964); for 1962-1968 from Census (1968c).

Number of  
Households,  
Millions

**Figure 12.** Total Households, Series 61, and the Percent Husband-Wife Households, Series 64, 1900–1968

## Primary Individual Households, 1940-1968

As the preceding page indicates, a housing unit may be a house, an apartment, a group of rooms, or a room. Households occupied by primary individuals are those wherein the household head lives alone or with nonrelatives.

There has been a great increase in the number of primary individual households over the last twenty years. The increase chiefly is due to the increase in the population, but it also is due to a change in household living arrangements which in turn is affected by the marital status of the population, the age distribution of the population, and the size of the institutional population and the Armed Forces.

Primary individual households, expressed as a percent of total households, indicates the relative increase in primary individual households.

The percentage has increased from below 10 percent in 1948 to almost 18 percent in 1968. Census Bureau projections of households to 1975 do not markedly increase this percentage (17.5-17.8 in 1970; 17.9-18.5 in 1975), but the trend in the percentage, shown in Figure 13, appears to point to larger increases in the percent of primary individual households.

Number of  
Households,  
Thousands

**Figure 13.** Primary Individual Households: Number and Percent of Total Households, 1940–1968, Series 65 and 69

## Average Population per Household, by Age and Color, 1955-1968

The average size of both white and nonwhite households has declined slightly since 1960. Nonwhite households remain considerably larger, on the average, than white households (approximately two-thirds of a person larger).

The average number of children (persons under 18 years of age) in white households has remained relatively constant, while the average number of children in nonwhite households has increased slightly in the twelve-year period (approximately one-fourth person per household increase).

In general the trends in average number of persons per household are relatively stable. The most significant feature of the graph is the larger nonwhite household, when compared with the white. If anything, the difference in the size of household between white and nonwhite is becoming greater.

Census Bureau projections of household size anticipate a continuing decline in the average number of persons per household to 1985, a decrease from 3 percent to 14 percent depending upon the assumptions.

Source: Series 70-81: data for 1955-1967, respectively, from Census (1956c; 1957b; 1958c; 1958d; 1960b; 1961a; 1962b; 1963d; 1965d; 1966a; 1967b; 1968e); for 1968 from unpublished material supplied by the U.S. Bureau of the Census.

Average Number  
of Persons

**Figure 14.** Average Population per Household, for Two Age Categories and by Color, 1955–1968, Series 70–73

### Average Size of Family, by Age and Color, 1955-1968

Increases in the average size of family, both white and nonwhite, have occurred since 1955. The nonwhite family has grown more in size than the white. In 1955, the average nonwhite family was 0.59 persons larger than the white. By 1967, it was 0.78 persons larger.

The lower lines on the graph show that the increase in the size of the nonwhite family may be attributed to children. In 1955 the number of children under 18 years in the nonwhite family exceeded the white by 0.54 children. By 1967, this difference had increased to 0.75 children. Meanwhile, as Series 80 and 81 show, the average number of adults in both white and nonwhite families remained approximately constant.

Sources for data presented in Figure 15 are cited on page 34.

Average Number  
of Persons

**Figure 15.** Average Population per Family, for Two Age Categories and by Color, 1955–1968, Series 76–79

## The Changing Composition of the Family, 1947-1968

The size and composition of the family in the United States change very slowly in the aggregate, but, owing to relatively high residential mobility of the population (approximately one-fifth moving to a different house each year), a fluctuating marriage rate (Figure 1), and other factors, changes in family composition do take place.

Figure 16 traces the changes in the percentage of families of various types. These trends may be summarized as follows: Husband-wife families have maintained relative stability as a percent of the total. Families made up of husband-wife-and-one other person and husband-wife-and-two other persons have declined slightly over the entire period. At the same time, families of husband-wife-and-three other persons are increasing. The small family consisting of husband and wife only is increasing. The age of head of husband-wife families indicates that increases have occurred, since 1957, in both new husband-wife families and in elderly couples, as is shown by the percentage distribution of husband-wife families for 1957 and 1967:

Age	1957	1967	Change
Less than 25 years	5.0	6.3	1.3
25-29 years	10.0	10.4	.4
30-34 years	12.4	10.0	-2.4
35-44 years	24.9	23.1	-.8
45-54 years	21.0	21.7	.7
55-64 years	15.3	15.7	.4
65-74 years	8.6	9.2	.6
75 years and over	2.8	3.7	.9

In addition to these changes in the percentages of different classes of families, the families with other male head, that is, wife not present, is declining. Concurrently, the percent of families with a female head is increasing, as also is the size of families with female head.

While the average number of children in families has increased and the average number of adults has declined very slightly, the net result has been a slight decline in the size of the family. In 1968 the average family was 3.68 persons (Parke, 1969: 6). The Census Bureau foresees a continued slow decline in average family size.

The present (1967) distribution of families by number of own children is presented in Table 1.

Source: Series 82-93: data for 1947-1967, respectively, from Census (1955c; 1950; 1951; 1952; 1953a; 1954; 1956c; 1957b; 1958c; 1958d; 1960b; 1961; 1962b; 1963d; 1965d; 1966; 1967b; 1968e); for 1968 from unpublished data supplied by the U.S. Bureau of the Census.

Percent of Married Couples Without Own Households,  
1940-1968

"Doubling up" of married couples in households with relatives or others was rather high during the immediate post-World War II period, when housing was in short supply. The percent of married couples living in a household with others, however, has continued to decline. In 1968 only 1.5 percent were not living in their own household.

The distribution by color, however, presents considerable disparity between white and nonwhite households, as the following table shows:

Table 2. Percent of Married Couples Living with Relatives,  
by Color, 1950, 1960, and 1967

Year	White	Nonwhite	Total
1950	4.2	8.2	4.6
1960	2.0	4.2	2.2
1967	1.4	3.2	1.6

Source: Census, 1968a: 2.

Source: Series 94-97: data for 1910-1957 from Census (1960c: Series A245-A247, p. 16); for 1958-1962 from Census (1965e: Series A245-A247, p. 3); for 1963-1968 from Census (1968c). Data for Series 97 was computed, 1910-1962.

Percent

**Figure 17.** Percent of Married Couples Without Own Household, 1940–1968, Series 97

## Households with Female Heads, by Color, 1930-1967

The percent of households with female heads has been increasing since prior to 1930, and now appears to be increasing fairly steadily. The increase may be attributed to increases among white households rather than nonwhite.

While the percent of white households with female heads is much lower than the percent for nonwhite households (in 1967, 18.9 percent of the white households, and 29.6 percent of the nonwhite), the percent of white households with female heads has increased during the past six years more steadily than the nonwhite. The long-term trend in both indices is increasing, but the nonwhite has not increased during the past six years and was actually lower in 1967 than in 1959.

Source: Series 98-100: data for 1900-1940 are computed from Census (1960c: Series A255, A261-A262, p. 16); for 1947-1953 from Census (1955c); for 1954-1967 from Census (1956c; 1957b; 1958c; 1958d; 1960b; 1961a; 1962b; 1963d; 1965d; 1966a; 1967b; 1968e).

**Figure 18.** Percent of Households with Female Heads, Total, 1930–1967, and by Color, 1954–1967, Series 98–100

## Percent Intact Marriages for Females, by Color, 1940-1967

In intact marriage, husband and wife are members of the same household, even if one spouse is temporarily absent on business, vacation, etc. Excluded from the category "intact marriage" are those marriages where one spouse was absent, separated, or "other."

On the next three pages graphs are presented for the following age groups:

14 years of age and over	Figure 19
14 to 19 years	Figure 19
18 and 19 years	Figure 20
20 to 24 years	Figure 20
25 to 29 years	Figure 21
30 to 34 years	Figure 21

The percent of marriages intact appears to be declining in both the long term and the short term, among both white and nonwhite females. Marriages of older females are more likely to be intact than those of younger females (see Series 101-126).

For each age group, the percentage of nonwhite marriages that are intact is smaller than the percentage of white marriages. The difference is greatest in the 25-29 age group, as the following for 1967 shows:

	White minus nonwhite percent- age of intact marriages
18 and 19	7
20-24	16
25-29	22
30-34	19
35-44	17
45-54	18
55-64	12
65-74	7
75 and over	12

The series for intact marriages of white females is relatively stable compared with nonwhite females. This partly is a function of the smaller sample of nonwhites in the Current Population Survey, producing percentages with higher sampling error than the series for white females.

## FERTILITY

### Net Reproduction Rates, by Color, United States, 1940-1967

The net reproduction rate combines both the fertility and mortality experience for the year and thus provides a fairly sensitive index of the effect of present rates on population change, excluding migration. The rate shows the average number of daughters that a cohort of 1,000 females would bear during their reproductive life, if they were to experience the prevailing age-specific mortality and fertility rates. A net reproduction rate of 1,000 indicates that present rates are sufficient to replace the population within a generation. A rate greater than 1,000 reflects a potential increase in the population within a generation. The amount of the increase may be judged by the formula  $NRR/1,000 - 1$ . For example, the 1966 rate:  $1,288/1,000 - 1 = .288$ , or a 28.8 percent increase in the population might be expected in a generation, if 1966 rates continue.

The total net reproduction rate changed its rate of increase after 1956, and began to decline about 1960. Enovid and other birth control pills began to be introduced about 1961, and the IUD at about the same time. Fertility experts do not attribute the decline solely to either of these innovations, but also attribute part of the decline to the achievement earlier in life of the size of family desired by the couple.

Because population growth has been great, both in the United States and in other countries, many have advocated that the rate of growth of the population should be reduced. While the NRR does not tell the whole story, it does provide a single sensitive measure of considerable significance. If it were to reach 1,000 and remain at 1,000, the goal of stationary population might eventually be reached.

The trend in the white NRR is approximately the same as the total, shown in the figure. For this reason only the total and the nonwhite are presented.

Rate

**Figure 22.** Net Reproduction Rate, Total and Nonwhite, United States, 1940 – 1967, Series 127 and 129, 1940 – 1959 corrected for underregistration of births, 1959 – 1967, registered births

The Number of Children Ever Born per 1,000 Women, by Age and Color, 1940-1969

To replace the population approximately 2,130 children should be born during the reproductive life of every 1,000 women, considering current mortality rates. In 1969, women 45 to 49 years of age had produced 2,665 offspring per 1,000, thus exceeding replacement of their generation by 535 offspring per 1,000 women.

The reproductive record of these women who have recently completed their childbearing is being exceeded by the next three younger age groups of women. Those 40 to 44 years of age in 1969 had already exceeded requirements needed to replace their generation by 829 births per 1,000, those 35 to 39 years of age had exceeded it by 928 births per 1,000, and the women 30 to 34 years of age had exceeded requirements by 593 births per 1,000, and each of these cohorts undoubtedly will have additional births before completing its childbearing.

In the chart at the right, fertility of all women 15 to 44 years has declined very slightly in recent years, but the indicators of fertility of the younger age groups, those 15 to 19 and those 20 to 24 years of age, have declined considerably during the past ten years. Fertility of the 25 to 29 age group of women also has declined, but that of women 30 to 34 years of age has not.

These indicators bear upon the timing of births by families, which, in turn, affects the rate of population growth. Women 30 and above in the current population began to have their families early and have continued to add to their families until late in the childbearing period. The present younger women appear to have reduced the number of children they are having early in life. If such reductions continue throughout their childbearing, the total offspring of these successive generations of women will begin to approach closer to the level needed to replace their generation in the population, and eventually to a slower rate of population growth.

Note: Replacement levels. The total number of children ever born to every 1,000 women necessary for population replacement has been estimated at various times, depending upon the prevailing rates of mortality. Based on the 1939-1941 mortality experience, 2,240 ever-born children were estimated as required for replacement of the generation (Census, 1966b). Using the 1949-1951 mortality experience, some 2,200 offspring were needed (Census, 1961b). The most recent experience suggests, 2,130 offspring per 1,000 women are required (Census, 1969d).

Source: The discussion above is based upon the analysis published by the Bureau of the Census (Census, 1969d). Data for Series 130-153 from Census 1969d, except for 1959 data which are from 1961b: 17.

per 1,000 Women  
Semi-logarithmic Scale

**Figure 23.** Children Ever Born per 1,000 Women of Four Age Groups for the Noninstitutional Population, 1954, 1964, and 1969, and for the Total Population, 1940, 1950, and 1960, Series 130-132, 137

Legitimate Birth Rates (based upon married women) and  
Illegitimate Birth Rates (based upon unmarried women)  
(registered live births per 1,000 females 15-44 years  
of age), 1940-1967

The fairly uniform secular trend of the illegitimate birth rate contrasts with the widely varying legitimate fertility rate (Figure 24). The latter is affected by the changing marriage rate, by the effects of World War II and the postwar period, by improvements in birth control methods, by the attainment of the desired size of family at earlier ages, and by other factors. While the annual incremental increase in the illegitimate fertility rate is declining (averaging 0.36 for the most recent five-year period as compared with 1.04 for the 1950-1955 period), the present rate represents more than 300,000 illegitimate births annually.

Series 155-161: 1940-1965 from National Center for Health Statistics (1968b: Table 1, p. 25); for 1966 and 1967 from unpublished material supplied by the National Center for Health Statistics.

Births per 1,000  
Females

**Figure 24.** Legitimate Birth Rate (based upon married women) and Illegitimate Birth Rate (based upon unmarried women)(registered live births per 1,000 females, 15–44 years of age), 1940–1967, Series 154–155

## Illegitimate Birth Rates, by Age of Mother, 1940-1967

Young unmarried women, aged 15 to 19 years, have a low rate of illegitimacy, one that has been relatively constant for more than ten years as shown in Figure 25. By contrast, unmarried women 20 to 24 years of age have had a rapidly increasing rate until 1960-1961, after which the rate has declined. The rate for unmarried women 25-29 years has increased rapidly throughout the time period shown, only declining after 1964. The rate for unmarried women 30-34 years of age also has increased rapidly, although the rate itself is lower than the rate for the two groups just mentioned. It increased to 1965, but declined during the two following years.

## Illegitimate Birth Rates, by Age of Mother and Color, 1955-1967

Figure 26 shows the trend since 1955 in the illegitimate birth rate for two age groups of mothers, 20-24 years and 25-29 years, the ages of highest incidence. The nonwhite rate is approximately seven times greater than the white rate for these age groups, and in 1965 there were 167,500 illegitimate non-white births and 123,700 white ones.

Trends in the two series show distinctive characteristics. The nonwhite rates moved rapidly higher to 1960, the rates then began to decline and now appear to be declining rapidly. The white rates, on the other hand, present a fairly steady and uniform increase for the age groups below 25 years.

The data presented below highlight several distinctive features of illegitimate births: second and higher order illegitimate births are more numerous among nonwhites than first order births; quite the opposite is the case among whites. Illegitimate births are more likely to be premature and the fetal death ratios also are higher among nonwhites. Illegitimate births are more likely to be delivered by midwives among both whites and nonwhites. These characteristics are shown below.

Table 3. Characteristics of Illegitimate Births, 1964

	White	Nonwhite
Total illegitimate births	114,300	161,300
Live-birth order: first	76,200	71,200
Live-birth order: second or higher	38,000	90,000
Ratio, illegitimate births per 1,000 live births	33.6	263.9
Metropolitan counties	36.5	266.0
Nonmetropolitan counties	29.6	260.6
Percent premature births (2,500 grams or less)		
Legitimate births	6.8	13.0
Illegitimate births	11.3	16.5
Percent of deliveries by midwives		
Legitimate births	0.4	8.2
Illegitimate births	0.8	11.8
Fetal death ratios (per 1,000 live births)		
Legitimate	13.0	25.7
Illegitimate	20.9	29.0

# Rates of Illegitimacy of Four Independent (five-year) Cohorts of Unmarried Women, 1940-1965

Each of the four cohorts of unmarried women shown in Figure 27 are in five-year non-overlapping age groups. The age of mother is identified by the letters located on the ordinate for the year when the cohort was within the specified ages. While the cohorts consist of females born during the same five-year span, the marital status may have changed over time and hence the individual unmarried females may not be identical throughout.

Each successive cohort presents a higher rate of illegitimacy than the same age group five years earlier. This is readily observed by tracing the position of each letter across the chart. The "a," for example, representing the 15- to 19-year-olds, increases as it moves across the time dimension.

An index of change in the rates is the ratio of the rate for an age group at one point in time to the rate of the same cohort five years earlier. For the cohorts illustrated, these ratios are:

Table 4. Index of Change in Illegitimacy Rates for Cohorts of Unmarried Women

Year when age 15-19 years	Ratio of Rates				
	20-24 yrs. to 15-19 yrs.	25-29 yrs. to 20-24 yrs.	30-34 yrs. to 25-29 yrs.	35-39 yrs. to 30-34 yrs.	40-44 yrs. to 35-39 yrs.
1960	2.61				
1955	2.63	1.24			
1950	2.66	1.35	.83		
1945	2.24	1.57	.83	.63	
1940	2.07	1.30	1.11	.64	.32

As these ratios tend toward stability, the rate of illegitimacy would appear to be increasingly predictable. For example, if the most recent ratios are applied, the cohort that was 15-19 years of age in 1965 would have an illegitimacy rate of 44 per 1,000 unmarried females 20-24 years of age in 1970, a rate of 54 per 1,000 unmarried females 25-29 in 1975, and a rate of 45 per 1,000 unmarried females 30-34 years of age in 1980. Following this procedure, the 1970 rates may be projected as follows:

Age	1970	1965	Expected increase
15-19 years	18*	17	1
20-24 years	44	31	13
25-29 years	50	49	1
30-34 years	41	38	3
35-39 years	24	17	7
40-44 years	6	4	2

\*Based upon the ratio of the 1965 15-19-year-old rate to the 1960 15-19-year-old rate, applied to the 1965 15-19-year-old rate.

Sources for data presented in Figure 27 are the same as cited for Series 155, page 54.

Births per 1,000  
Unmarried Females

**Figure 27.** Illegitimate Birth Rates of Four Independent (5-year) Cohorts of Unmarried Women, 1940–1965, Series 156–161 (Illegitimate Births per 1,000 Unmarried Females)

## Changes in the Rates of Illegitimacy

The cohort rates of illegitimacy, illustrated in Figure 27, provide a basis for measuring change. For example, the rate for mothers of a given age, say 15-19 years, may be compared with the rate for the same age group five years earlier. This gives the magnitude and direction of change in rate. To illustrate, with the 15-19 years-of-age group:

Rate, 15-19-year-old mothers, 1940	7.4
Rate, 15-19-year-old mothers, 1945	9.5
Change 1940 to 1945	2.1

The change in the rate is 2.1 illegitimate births per 1,000 single females 15-19 years of age, 1940 to 1945. In a similar manner, to a given time the changes in rates for all five-year age groups may be determined. Because the data are in five-year age groups, independent (non-overlapping) comparisons may be made every five years. See Table 5, A through E, for these comparisons.

Figure 28 shows the trend in the sum of changes of six age groups (15-44 years), ending with 1967. The aggregate change of six age groups over successive five-year periods increased to 1956 (See Table 5, C). The increase in the total illegitimate rate, 1951 to 1956, also achieved its greatest increment during the 1951-1956 period, and since has increased in smaller increments.

In the most recent period, 1962-1967, the rate for all age groups declined except that of the 15-19 year olds. Because of the greater numbers of single females in these ages, an increase occurred in the total rate (shown in the first column, Table 5). To effect real reductions in the total rate, the illegitimacy rate among the 15-19 year olds must be decreased.

The arrangement of rates in the manner shown in Table 5, in non-overlapping, independent 5-year observations ending each year, provide an orderly basis for evaluating change. Increments presented in the first column, the total rate for 15-44 year old unmarried females, is the best summary measure, but a change in the rate among the 15-19 ages will have a greater effect upon the total than changes in other age groups.

Aggregate Change

**Figure 28.** The Sum of Changes in Illegitimate Birth Rates Over the Previous 5-Years, for Six Age Groups, Successive 5-Year Periods Ending 1967, Series 156–161 (Table 5, A–E)

Table 5. Changes in Rates of Illegitimacy over 5-Year Periods

Period	Amount of change over the preceding 5-year period							Sum, all ages
	15-44 years	15-19 years	20-24 years	25-29 years	30-34 years	34-39 years	40-44 years

## Infant Mortality Rates, by Color and Sex, 1920-1967

Dramatic decreases in infant death rates from 1920 to 1950 are observed in Figure 29. Since 1950, however, the number of infant deaths (under 1 year) per 1,000 live births has declined at a greatly reduced rate.

The total rate, not displayed on the graph but presented as Series 174, declined by 56.6 deaths from 1920 (when the rate was 85.8) to 1950. From 1950 to 1960 the total rate declined only 3.2 deaths per 1,000. From 1960 to 1965, the rate declined only 1.3 deaths, but in the next two years there was an additional reduction of 3 deaths per 1,000 live births.

Despite these recent gains, infant mortality in the United States is greater than in some other countries. In Sweden, for example, in 1965, approximately 15 infants died per 1,000 live births. At that time United States rate was slightly under 24.

The infant mortality rate for males exceeds the rate for females, apparently a common human phenomenon partly compensated by nature through a sex ratio of approximately 105 male live births per 100 females (in 1966).

On the other hand, the rate for nonwhites persistently exceeds the rate for whites. This differential was nearly 50 infant deaths per 1,000 in 1920 and now has decreased to approximately 16 (1966). In 1966, the ratio of the nonwhite to the white rate was 1.82, showing that there is much room to reduce the nonwhite rate.

An official of the Federal government has discussed a total infant mortality rate of 15 as a goal for 1976, but does not think it can be achieved without an extraordinary effort. (Forthcoming, 1970, NICHD discussion of key issues in infant mortality.)

## DEPENDENCY

### Children Under 18 Years of Age per 100 Population 18-64 Years of Age, 1940-1968

A dependency ratio reflects the child-rearing task of a population in relation to its adults of working ages. As Figure 30 shows, support of children is not uniformly borne throughout the United States. The Northeast has always been more advantaged than the other regions, and the South has been more disadvantaged.

The rise in the dependency ratio, shown here by the increase from 1950 to 1955 and thereafter, may be attributed to the increase in the number of births that began in postwar 1946 and continued increasing to 1961.

The decline in the dependency ratio following 1964 was due to the passing of the 1946 birth cohort out of the dependent category (under 18 years of age) into the adult category. The ratios are likely to continue to decline slowly to 1979, and more rapidly thereafter, for in 1979 the largest cohort of births will become 18 years of age (4,268,000).

The region with the highest dependency ratio, the South, has greatly improved its status relative to the other regions. In 1968 its ratio was not greatly different from that of the West and North Central regions. The Northeast, however, continues to maintain an advantage in having fewer children to rear and educate.

The dependency ratio presented was selected because the estimates by region from the Current Population Survey are aggregated to the age groups used here. The more conventional ratio is the children under 20 years to the population 20 to 64 years (Bernert, 1958: 166-168). The older population, 65 years and over, may also be expressed as a ratio to the working population, to provide an indicator of the dependent older population.

Source: Series 183-187: data for 1940 from Census (1943: Table 26, pp. 96-97); for 1950 from Census (1956b); for 1955 from Census (1957a); for 1960-1966 from Census (1968d); for 1967-1968 from Census (1969b).

**Figure 30.** Ratio, Persons Under 18 Years of Age per 100 Population 18–64 Years of Age, by Region, for the United States, 1940–1968, Series 184–187

Percent of Children Under 18 Years of Age Not Living with  
Both Parents, 1950 to 1966, and by Color, 1957-1966

Approximately 14 percent of children under 18 years of age live with one or none of their parents. It appears that the percentage is increasing among both white and nonwhite children, but recent observations, being based upon sample surveys, are subject to sampling errors and the year-to-year differences are not sufficiently large to show evidence of a distinct trend.

The nonwhite rate, however, is approximately three times larger than the white rate, and the trend shows no signs of decreasing.

As the table below for 1960 shows, the children of the city and of rural nonfarm areas are more likely to be in homes where one or both parents are not present than are rural children.

Table 6. Percent, Children Under 18 Not Living with Both  
Parents, by Residence and Color, 1960

Residence	Total	White	Nonwhite
Total	13.2	10.0	33.7
Urban	13.8	10.3	35.1
Rural nonfarm	12.8	10.1	32.7
Rural farm	9.8	6.6	26.5

Source: Census, 1962c: Table 79, pp. 1-210.

Broken homes have been found to be associated with delinquent behavior of adolescents (Rodman and Grams, 1967: 196-197). The broken home, however, is not necessarily an indicator of family disorganization. "Psychologically" broken homes, having all members present but fraught with discord, have been shown also to be associated with delinquent behavior. However, this structural factor alone--one or both parents not present--undoubtedly indicates inadequacies of home and family.

## Children Involved in Divorce, 1953-1967

The figure at the top in Figure 32 shows the average number of children per decree of divorce or annulment, 1953 to 1967. The rate increased steadily to 1964, and has remained relatively constant since then. The present stability of the rate may be a consequence of the declining birth rate.

The figure at the bottom in Figure 32 presents the children involved in divorce actions per 1,000 children under 18 years of age. This rate was fairly constant to 1958 and thereafter began to rise rapidly.

The number of children involved in divorce has increased an average of 34,000 each year since 1960. In 1967 an estimated 701,000 children were involved in divorces.

Source: Series 191-193: data for 1953-1965 from National Center for Health Statistics (1968c: Table 2-9, pp. 2-9); Series 191-192 for 1966 and 1967 from National Center for Health Statistics (1969b: Table 3, p. 2); Series 193 for 1966 and 1967 was computed from National Center for Health Statistics (1969b: Table 3, p. 2) and Census (1969b).

## DIVORCE

### Divorces and Annulments per 1,000 Married Women 15 Years of Age and Over, 1920-1967

Being based upon the divorces granted within a year and the number of married females, this is a "period" statistic. As such, the series responds to general socioeconomic conditions. With rising prosperity, the divorce rate increases, and it declines during periods of serious economic depression. The excessively high rate around 1946 (Figure 33) results from the personal and social dislocations during and following World War II. However, the 1946 rate is abnormally high, even for a postwar period, since "many marital difficulties of the war years did not reach the courts until after the close of hostilities, thus greatly increasing the total number of divorces for 1946 . . ." (Carter and Plateris, 1963: viii).

Despite fluctuations, the rate undoubtedly shows a long-term secular increase. Uniformly distributed over the 45 years (the low point of 1922 to 1967) the annual increment would be approximately 0.1 per year. In terms of 1967, when 523,000 divorces and annulments were granted, the 0.1 increment in the rate per year represents an additional 4,600 divorces. Actually, 1967 divorces and annulments exceeded 1966 by 24,000, an increase approximately five times greater than one would expect from the long-term trend.

Source: Series 94: data for 1920-1965 from National Center for Health Statistics (1968c: Table 2-1, pp. 2-5); for 1966 and 1967 from National Center for Health Statistics (1969b: Table 2, p. 2).

## A Lead Indicator of the Number of Divorces, 1954-1967

In March of each year the Current Population Survey collects information on the marital status of the population 14 years of age and over. The number of married females separated from spouse provides a rough index to the number of divorces the following year. The "separated" category, in the Census definition, includes "persons with legal separations, those living apart with intentions of obtaining a divorce, and other persons permanently or temporarily estranged from their spouse because of marital discord" (Census, 1968a: 5-6). It does not include other types of separations, such as husband in the Armed Forces, or in-migrants whose spouse remained in other areas, or a married women whose husband is in an institution.

While the estimate of the number of married females separated from spouse is made from information collected in household interviews, the number of divorces during a year is reported through the vital statistics systems of the several states to the National Office of Vital Statistics.

In Figure 34, the numbers identify the sequence of the "observations" from 1, which represents the number of females separated from spouse in 1954 and the number of reported divorces in 1955, to 13, representing the 1966 separations and the 1967 divorces. A roughly curvilinear relationship is suggested by the line.

Source: Series 195: data for 1954-1967 from National Center for Health Statistics (1969b: Table 2, p. 2); Series 196: data for 1954-1967 from, respectively, Census (1955a; 1955b; 1956a; 1958a; 1958b; 1959a; 1960a; 1962a; 1963a; 1965a; 1965b; 1967a; 1968a).

## Estimated Divorce Rates by Marriage Cohort, 1949-1967

Figure 35 presents cumulative divorce rates by marriage cohort. The first upright line of the graph represents the cumulative percentage of divorces among those who married in 1949, successively over the first nine years of marriage. Only cohorts married in 1958 or before have completed the entire nine years of marriage. The most recent observation, the percent of divorces among 1967 marriages occurring before the end of 1967, is represented only by the dot on the 1967 ordinate, since only the first one-half year of experience is available.

At the end of its nine-year period, 15.8 percent of the 1949 cohort of marriages had ended in divorce. Over its first nine years of marriage, 17.8 percent of the 1957 cohort had been divorced. The difference, about two percentage points, represents the maximum increase in the cohort divorce rate. The rate of the 1958 cohort was slightly lower.

In Figure 35, the more recently married cohorts may be compared with older cohorts with the same number of years' marriage experience. For example, the fifth set of dots from the bottom shows the experience after four years of marriage. (The lowest dot represents the percentage of divorces and annulments before the end of the first year of marriage.) After four years of marriage, the percent divorced varies just above 10 percent. For the cohorts with four years' experience, the divorce rate appears to have been falling to calendar year 1960, and since then has increased slightly. This portends a slight increase for the ninth-year divorce rate in 1972 for the 1963 cohort.

The data are estimates based upon the records of states in the Divorce Registration Area. As such, the estimates for the United States are not completely reliable. Some error may be attributed to the unrepresentativeness of the states in the Divorce Registration Area. A sample study of all state divorce records was made in 1960 enabling a test of the estimate of divorces by duration of marriage (see National Center for Health Statistics, 1964a; Carter, Ortmeier and Plateris, 1962). The DRA estimate was within one standard error of the estimate based upon the sample in six of the ten years-of-marriage duration categories. In two others it was within two standard errors, and in one it was slightly more than two sampling errors. In the latter case, the DRA estimate was 10 percent lower than the sample estimate. As more states are admitted to the DRA, this divorce indicator will become more representative and reliable.

While the period series (Figure 33) and the cohort series (Figure 35) each reflect different circumstances and cannot be directly compared, the cohort series, enabling a comparison of the divorce rate of couples with the same number of years of marriage experience, undoubtedly is the more sensitive index of family dissolution.

Source: Series 197-206 for 1949-1965 are computed from data in the various annual volumes of Vital Statistics of the United States (National Center for Health Statistics, 1951: Table CW, p. lxiii; 1953: Table 9, p. 30; 1954: Table 15, p. 97; 1955a: Table 16, p. 84; 1955b: Table 16, p. 76; 1956: Table 16, p. 77; 1957: Table 16, p. 77; 1958: Table 16, p. 77; 1959: Table 22, p. 95; 1960: Table 23, p. 110; 1961: Table 23, p. 91; 1964a: Tables 4-7, pp. 4-6; 1965a: Tables 4-7, pp. 4-7; 1965b: Tables 2-16, pp. 2-15; 1967b: Tables 2-17, pp. 2-15; 1968f: Tables 2-17, pp. 2-15; 1968c: Tables 2-17; pp. 2-15). Data for 1966-1967 are computed from unpublished material of the National Center for Health Statistics.

## WORK AND INCOME

### Labor Force Participation Rates of the 20-24 Year Old Population, by Sex and Marital Status, 1957-1968

The labor force participation rate is the percentage in the labor force who are working or looking for work. The association of marital status with participation in the labor force is shown in Figure 36 for the 20 to 24 age groups of males and females.

High rates of participation in the labor force characterize married men and men who are separated, divorced, or widowed ("other" males). Single males, on the other hand, have considerably lower rates of participation in the labor force. Part of the decline in participation of this age group, illustrated by the decreasing rate for single males since 1960, may be attributed to an increasing rate of enrollment in school (which, for males and females 20-24 years of age increased from 13 percent in 1960 to 21 percent in 1968).

In contrast to males, females 20-24 years of age who are single are more likely to be in the labor force than are married females. However, the trend for married females is an increasingly higher labor force participation rate.

Source: Series 207-212: data for 1957-1967 from U.S. Department of Labor (1968b: Table 4, p. 31); for 1968 from unpublished material supplied by the Bureau of Labor Statistics, U.S. Department of Labor.

Percent

## Unemployment Rates by Marital Status, Sex and Color, 1962-1968

Unemployment rates for nonwhites are persistently higher than unemployment rates for whites. Trends in recent years, however, show a decline in unemployment for all sex, color, and marital status categories. In addition, the nonwhite unemployment rates are approaching the level of the white rates, except the rate of single nonwhite persons.

Among males, marital status makes a difference in rates of unemployment. Single persons are unemployed at higher rates than "other" married males (widowed, divorced, and married, spouse absent). The "other" married category has higher unemployment rates than the married, spouse present, category. The responsibility associated with marital status evidently has some effect.

Marital status among females, however, produces somewhat different unemployment effects. Among nonwhite females, the unemployment pattern resembles that of males: highest unemployment rate is among the single and lowest (until 1967) among the married. The reverse, however, characterizes white female unemployment: single females have the lowest unemployment rate while "other" marital status has the highest. It is quite apparent, however, that unemployment rates differ by marital status least among white females, while they differ most by marital status among nonwhite males.

As the unemployment rate among married nonwhite males with wife present has declined and, in 1967, reached about three percent, the unemployment rate among the married nonwhite females, spouse present, has increased. During the same period the rate for the married white females, spouse present, followed the same pattern. The labor force participation rates among married females whose husbands are in the labor force, however, has not declined (U.S. Department of Labor, 1968a: 251).

## Mean Income of Families and Unrelated Individuals and a Measure of Income Distribution, 1947-1966

The mean money income in constant dollars of families and unrelated individuals is shown in Figure 40. The mean declined to 1949 and then began to increase. Except for two periods of recession, 1954 and 1958, the mean has continued to increase to the present time. From 1948 to 1966, the trend represents a 132 percent increase in actual purchasing power of the average family.

The lower line on the graph traces changes in the Gini ratio. If this ratio were zero, money income would be distributed equally among the units (families and unrelated individuals) of the population. A decline in the Gini ratio signifies a more equitable distribution of income.

The range of changes in the Gini ratio, as shown at right, has been quite small, only 0.2, and the most recent observation, 1966, is not the lowest recorded. The ratio declined during the prosperous period, 1954 to 1957, and also has been declining during the period of affluence since 1961. Peaks of the index in 1949, 1954, and 1961 coincided with troughs in the business cycle, although there was not a peak in 1958 when business activity also was low. The changes in the income distribution reflected by these trends are presented in Figure 41.

Although not presented in Figure 40, the values for 1967 and 1968 are included in the tabular Series 225-232, showing a continuation of the trends illustrated.

Source: Series 225, 227, 229 and 232 are from Merriam (1968: Table C, p. 790); Merriam obtained special tabulations from the March Current Population Survey for the respective years; 1967 was computed from (Census 1969c: 32); 1968 was computed from unpublished data, courtesy of the U.S. Bureau of the Census. Series 226, 228, 230 are computed by applying the implicit price deflator for personal consumption expenditures (Council of Economic Advisers, 1969: Table B-3, p. 230) to Series 225, 227, 229; Series 231 is the difference between Series 228 and 230.

Income,  
Constant Dollars

**Figure 40.** Mean Income of Families and Unrelated Individuals in Constant (1958) Dollars, 1947 – 1966, Series 226, and the Gini Ratio, 1947 – 1966, Series 232

## Money Income of Families and Unrelated Individuals, 1947-1966

For Figure 41, families and unrelated individuals (living alone or with a nonrelative) were ranked from low to high according to the amount of their money income. The ranks were then divided into five segments of equal size. The value plotted on the lower line is the amount of money income of the upper bound of the lower fifth of the families, and, at the top of the graph, the lower bound of the upper fifth (or, what is the same thing, the upper bound of the 4th fifth). The trends, thus, show how the well-to-do families are faring and how the lower income families are faring. Income is expressed in constant (1958) dollars so that the purchases for personal consumption per dollar are constant across time.

The lower line on the graph shows a slowly increasing income for the lower fifth of families. From 1954 to 1966, money income in constant dollars increased 58 percent, an average of 837 constant dollars per family.

The upper line on the graph shows the trend for the lower bound of the upper fifth of the families. From 1954 to 1966, the money incomes increased 46 percent, an average increase of 3,048 constant dollars per family.

The lot of upper-income families was obviously improving more than that of lower-income families.

The line in the middle of the figure shows the disparity or the difference between the upper and the lower money incomes in constant dollars. If the disparity were constant across time, this line would be horizontal.

Data for 1967 and 1968 became available after Figure 41 was drawn and has been added to Series 225-232, but does not appear in the figure.

Source for data presented in Figure 41 is cited on page 88.

Income,  
Constant Dollars

## POVERTY

### Families and Unrelated Individuals Living in Poverty, by Color, 1959-1967

The Social Security Administration has developed an index of poverty. The annual income of a family at the poverty level varies with family size, age, and sex of the head of the household, and whether the family is a farm or nonfarm resident. For example, the poverty-level criteria used in March 1967 varied from \$1,105 for a one-person farm family with a male head over 65 years of age, to \$5,440 for a nonfarm family of seven or more members with a male head. Since level is based upon the assumption that one-third of income is spent for food, the index is revised annually to adjust for changing prices.

The trend in the number of families and of unrelated individuals living below the poverty level, by color, is shown in the upper Figure 42. Since 1959, the number of nonwhite poverty-level families has declined 26 percent, while white poverty-level families have declined 39 percent. The change in the number of unrelated individuals in poverty has been small. The number of nonwhite unrelated individuals living in poverty has declined 7 percent and the number of white unrelated individuals in poverty has declined 3 percent.

The percentage of families living in poverty, as well as the total number, has declined, as the lower graph illustrates.

The details are presented in Series 233-244.

or Unrelated Individuals,  
Millions

Percent

**Figure 42.** Families and Unrelated Individuals below the Poverty Level, by Color: Number and Percent of Total Families, 1959–1967, Series 234–235, 237–238, 240–241, 243–244

## Characteristics of Poverty Families, 1959 to 1967

Table 7 identifies some of the characteristics of poverty families and illustrates the changes between 1959 and 1967.

Most poverty families, 51.7 percent of them, are white with a male head. There are even more white females living alone or with nonrelatives who are in poverty, making up 62.9 percent of the unrelated individuals in poverty. Most children who are in poverty families are in white families with a male head.

The rate of poverty (the percent of total families that are in poverty) is higher for nonwhites than for whites. For both color groups the rate of poverty is greater for families with a female head than a male head.

In general, poverty declined during the period 1959 to 1967: a reduction of 36 percent of the families, 36 percent of the children, and 4 percent of unrelated individuals. However, the number of poverty families increased among non-white families with female heads and among nonwhite females living as unrelated individuals.

Source: Census (1968g: Table C, p. 5; 1968h: Table 6).

Age, Sex, Color, and Household Status of Family Units in  
Poverty, 1966

Table 8 presents the characteristics of poverty units, families and unrelated individuals.

In coping with poverty in 1966, nearly eleven million family units were to be considered. Nearly two-fifths of these were 65 years of age and over. Seventy-seven percent were white. Forty-four percent were individuals living alone or with nonrelatives ("unrelated individuals"). Thirty-nine percent were women. Nearly ten percent were under 25 years of age.

Table 8 does not include the population of the households in poverty. It counts only the heads of households and the number of "unrelated individuals" in poverty. As such, it represents family units that might be the "targets" of programs to decrease poverty.

Source: Census (1968g: Table 7, pp. 22-24).
